Current Postseason Population Management Objective: 20,000

Management Strategy: Recreational

2012 Postseason Population Estimate: ~15,541

2013 Proposed Postseason Population Estimate: ~15,899

Herd Unit Issues

Energy development on crucial deer habitat is a looming issue for this herd. Extensive development has occurred over their range. Xeric environments and limited high quality

fawning habitats greatly affect deer productivity in several areas in this herd. This limited fawning habitat will affect the ability of fawns to evade predation by coyotes. Winter range condition is a major concern, much of which is in checkerboard ownership, limiting treatment options. Winter severity every three to five years is a major limiting factor for this deer herd. This is especially true in the western part of the herd around Evanston, Fort Bridger and Leroy. The eastern portion of the herd around Cedar Mountain experiences a rain shadow effect and has not been affected by severe winters in the last 10 years.

Highway mortality and impediment of migration is a significant issue in this herd unit. Mule deer have to cross highways to migrate to crucial winter ranges in several locations. In the Leroy area mule deer are crossing Interstate 80 to get to and from important winter ranges. Deer fencing is present in most of this area but deer crossing structures are limited and the fence is ageing and showing some signs of wear. Deer must cross Highway 414 in several areas between Mountain View and McKinnon to migrate to summer and winter ranges. Mortalities are common in those areas. The most significant area of issue is Wyoming Highway 189 between I-80 and Kemmerer. A large segment of the herd must cross this highway to get to winter ranges. Mortalities are very common due to heavy traffic on the roadway, and deer losses are exceeding 200 during some winters. This issue is likely to become much larger due to the construction of a new coal mine in this section of the road which will increase traffic considerably. Construction of this mine is currently on hold due to economics, but infrastructure is in place to begin operations.

Weather

Weather during 2012 and into 2013 was extremely dry and warmer than normal. The winters of 2011-2012 and 2012-2013 were mild with low snowpack resulting in good over winter survival. However, the dry spring and summer of 2012 negatively impacted summer and winter range forage production. Conditions were better at higher elevations but deer distribution was greatly affected.

Habitat

Habitat data collection has been inconsistently collected in this herd unit and has been absent in the recent past.

Field Data

The winter of 2010/11 was very severe in some areas and the population in the western part of the herd unit declined significantly due to it. Mortality surveys at the LeRoy winter range complex showed significant fawn and adult doe mortality. However, conditions were much milder in the eastern part of the herd unit. A radio collar study in that area showed a 92% survival rate from December of 2010 to December of 2011, a very high survival rate for mule deer does.

Classification data is collected yearly by helicopter in Hunt Areas 168, 132 and 133. Sample sizes are very good with over 1,400 deer classified annually. Post season buck ratios in 2012 were good with 26 bucks per 100 does. It is interesting to note that although yearling buck ratios were very low at 7:100, adult buck:doe ratios were high at 19:100.

Fawn:doe ratios in the herd unit as a whole were within the average for this herd over the last six years at 62:100. This is below where we would like to see them. The low fawn recruitment in this population is of very high concern. It may be due to several factors including winter range habitat condition, summer range habitat condition, elk competition on summer habitats, neonate predation on summer ranges, aspen stand condition on summer habitats, limited areas of

effective parturition habitats and doe age structure. We would like to improve future fawn:doe ratios through habitat improvement and predator manipulation to promote growth of this herd.

Fawn ratios in Hunt Area 132 are concerning with an observed 2012 postseason ratio of 54:100. This ratio is too low to allow for population growth, or maintenance. Hunt Area 132 consists of xeric habitats with low productivity potential when compared to the rest of the herd unit. It also has small, patchy areas of suitable fawning habitat, making newborn fawns more susceptible to predation, particularly from coyotes.

Harvest Data

The hunter harvest from seasons recently offered for mule deer do not impact overall population size, recruitment or productivity, and only influence buck:doe ratios, which are at the high end of recreational management criteria. Doe harvest is only allowed by youth hunters and in a very limited Type 7 season on irrigated lands. Overall female harvest is negligible. Harvest has fluctuated greatly over the past five years due to changes in population from winter severity and fluctuations in weather conditions during the hunting season.

Population

The Uinta mule deer herd was not modeled successfully for a number of years due to unknown amount of interchange with neighboring Utah, and reduced flight budgets preventing annual aerial surveys. We have begun scheduling this herd unit on an annual basis for survey dollars, and radio collar information suggests interchange is less than we previously thought (but does still occur).

We feel somewhat confident in this model since it is consistent with field information and seems reasonable. However, some caution should be used since this an interstate population with some interchange across state boundaries. Recent radio collar data documents over 12% interchange. This is far lower than we once expected. Continued radio collar work would help further determine the extent of these movements. The TSJ,CA model was selected due to the low Relative AICc score and its good fit with the data. The TSJ,CA model fits very well with mule deer population dynamics in this type of system.

In 2012 the Department switched from POP-II models to an Excel spreadsheet model. Since these are new models they are going to be under development and subject to extensive refining. They will likely change over time with new data.

The model predicts a post-season population of around 15,541 mule deer in 2013. This is a decrease in the population from 2010 levels. This reduction is substantiated by hunter comments, winter mortality surveys and anecdotal field observations. This supporting information gives us some confidence in model results. However, the trend modeled from 2010 levels (16,667) is not very realistic considering the severity of winter mortality observed on the western winter ranges where the vast majority of the deer herd winters. The trend since that period should have shown a more precipitous decline.

Management Summary

The 2013 season in hunt areas 132, 133 and 168 will allow for 11 days of general antlered deer hunting opportunity. This is a reduction of three days from the standard 14 day season we strive to offer. That reduction cuts the second weekend off of the hunt and ends it on a Friday. In consideration of youth hunting opportunity we leave a youth season open through that second weekend. This will allow youth to hunt two weekends.

Due solely to its popularity with local sportsmen, an antler point restriction will be maintained in hunt area 132. Additionally, a handful of doe-fawn licenses will be maintained in the herd unit to address the number of deer that are living year round on irrigated fields and give landowners an opportunity to have some harvested. The population objective and management strategy were last revised in 1997.

Management Evaluation

Current Management Objective: 11,750

Management Strategy: Special

2012 Postseason Population Estimate: ~6,200

2013 Proposed Postseason Population Estimate: ~6,300

The post-season population objective for the South Rock Springs mule deer herd is 11,750 deer under special management. The objective for this population was changed from 10,000 deer to 11,750 when the South Rock Springs and Black Butte herds were combined in the 1980's.

Herd Unit Issues

This herd has been well below this objective since the objective was set in the 1980's and most likely will continue to remain below objective for the foreseeable future. Current population estimates suggest this herd may be around 6,200 deer after the 2012 hunting season with a slowly increasing trend. The lack of growth in this herd despite very conservative hunting seasons can be attributed to poor fawn recruitment year after year. Observed fawn to doe ratios for this herd has averaged only 60 fawns per 100 does for the last decade. This level of juvenile recruitment is adequate for population maintenance, but does not allow for population growth.

Weather

Tougher than normal winter conditions during the 2010-2011 winter resulted in higher than normal over winter mortality in this herd. However, a significant portion of the herd was able to migrate south into Colorado and Utah to milder conditions than many other herds in southwest Wyoming. Because of this, the South Rock Springs herd probably experienced only slightly higher than normal winter mortality based on observed yearling buck ratios in the post-hunt classifications. The 2011-2012 winter by comparison for the most part significantly more mild than the previous winter and was relatively dry. The summer of 2012 was extremely dry with little summer precipitation. This lack of moisture was especially evident in areas of the herd unit below 8,000 ft, while the higher elevation parturition areas for the herd unit received enough snow and summer precipitation to allow for plant growth. This probably resulted in fewer fawns dying to cold, wet conditions during the early summer and could be the cause for the slightly improved fawn ratios seen in 2012. The drought conditions at the lower elevation winter ranges of the herd unit will probably affect this herd to some extent most likely in the form of lower fawn ratios in 2013 caused by poorer condition of does during gestation.

Habitat

The Green River aquatic habitat biologist has established six aspen regeneration monitoring transects throughout the South Rock Springs Mule Deer Herd unit. These transects are designed to evaluate browsing impacts from ungulates, primarily elk on young aspen. Two transects were established on Little Mountain in 2007 as well as four additional transects that were established in 2009, one each on Aspen and Miller Mountains and two in the Pine Mountain area. These transects were read each summer since their establishment..

A detailed accounting of the technique and results from these monitoring efforts can be found in the aquatic habitat annual report. In general, this method compares the height of the initial growth point for the current year's terminal leader to the height of the tallest previous terminal leader branch that was killed as a result of browsing. A positive Live-Dead (LD) value suggests growth of young trees, while a negative value or value near zero suggests that browsing may be suppressing tree growth. Results of monitoring efforts are presented in the following table (Table 1) taken from the aquatic habitat annual progress report, but in general, four of the six sites showed negative LD values for 2012, which can most likely be attributed to decreased moisture during 2012 compared to previous years.

Table 1. Trends in aspen regeneration LD Index values (vertical inches) for LME 2009-2012

Monitoring site	2009	2010	2011	2012
Pine Mt/Red Ck.	-4.1	-2.4	-0.5	-3.0

Little Mt./West Currant Ck.	NA	-17.6	+4.2	0

Field Data

This herd was classified from the ground during November and December 2012. The total number of deer classified for the herd unit was 1,076 deer. The resulting ratios from the ground classification effort were an observed ratio of 60 fawns per 100 does as well as 33 total bucks which included 10 yearling bucks per 100 does. This observed fawn ratio is generally in line with average ratios for this population.

Harvest Data

In general, the South Rock Springs Mule Deer Herd continues to maintain good hunter success. The success rates for the two hunt areas in this herd unit were 77% for Hunt Area 101 and 83% for Hunt Area 102 in 2012. These success rates are typical for this herd unit with the success rate showing a generally stable trend over the last several years.

Because the South Rock Springs Mule Deer Herd is a special management herd and because of its local importance, successful hunters are asked to voluntarily submit tooth samples for cementum annuli ageing analysis. Successful hunters submitted 132 samples for analysis from the 2012 hunting season. Based on those samples, the average age of harvested bucks was 4.5 years old in 2012. The average age of harvested bucks was 5.0 years old in 2010 and 2011, the 2009 average was 5.2 years old and 5.1 years old in 2008. Based on hunter submitted tooth samples, the oldest deer harvested during the 2012 season were four 8.5-year-old bucks; identical to what was submitted from the 2011 hunting season.

Population

The model for this herd tracks only moderately well to poorly with observed data in particular with the observed buck ratios, and sharing this herd with Colorado and Utah continues to decrease its overall reliability. The model selected for this herd is the time-specific juvenile survival model based its ability to produce the most realistic estimate for this population and does the best job of aligning simulated buck ratios to observed data. Additional information from the harvest survey, classifications, and reliable age data from lab-aged teeth from hunter-harvested deer combined with the model help in management of this popular and locally significant herd.

Management Summary

The 2013 hunting season is similar to how this herd has been managed since 2007 and is identical to the 2012 season structure. Despite the conservative seasons that have been set for this herd unit, observed buck to doe ratios are at the lower end allowed for a special management herd and public desires for higher buck ratios has led to frequent requests to decrease the number of licenses issued especially in Hunt Area 102. However, classifications compared to the number of licenses issued over the past 14 years, when there has been no issuance of doe

licenses, shows little correlation between license issuance levels and postseason buck to doe ratios. The most likely explanation for this is emigration of young bucks out of the state, but that hypothesis is based on speculation and deserves study to attempt to quantify if emigration is occurring and if it is occurring, at what level. It is possible that young bucks could be moving into Utah where the average age of bucks is less than in the Wyoming portion of the herd. This is suggested by the fact that the model does a poor job of aligning simulated and observed buck to doe ratios.

Herd Unit Issues

The Baggs mule deer herd is below the objective of 18,700 (which was established in 1986) and our current management strategy is to increase herd size.

Oil and gas development associated with the Atlantic Rim Project continues to impact this deer population, and impacts are increasing as the size of this development increases. Additionally, within 2 years, we expect to see the development of the largest wind energy project in North America, the Chokecherry-Sierra Madre Wind Project. A recently published study clearly outlines negative impacts of the increase in oil and gas development activities on migrating mule deer within the Baggs herd unit (Sawyer et al 2012). The study found that mule deer migrated quicker through areas with high levels of development and spend less time in stop over sites. In addition to the Atlantic Rim project, many parcels of public land on the west side of the Sierra

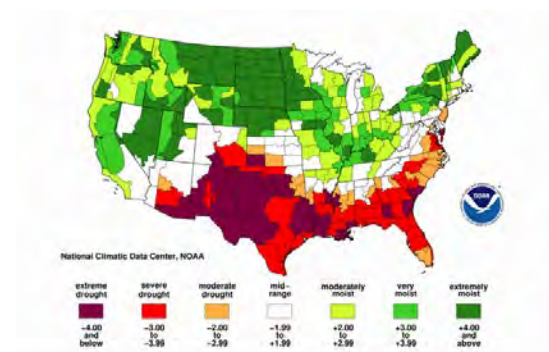

Madre mountain range have been leased for oil and gas development, as has the bulk of this population's winter ranges. Energy developments and proposals in this herd unit range from traditional oil and gas developments to coal bed methane, in-situ uranium, and wind energy developments. In addition, elk and feral horse use of winter range habitats is increasing, potentially to the detriment of this species.

Weather

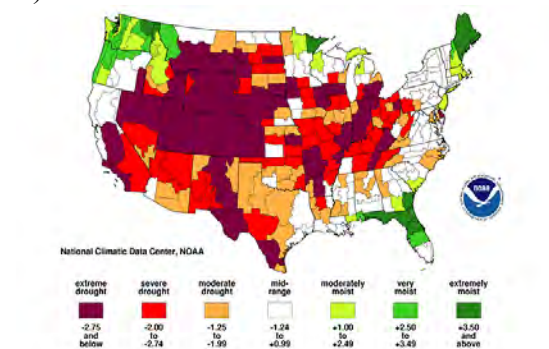

Within the last several years, we have seen extreme weather conditions within this herd unit. This has lead to variation in fawn and adult survival, fawn production and hunting conditions. In 2010-11 moisture levels were at record highs with high snow levels, followed in 2011-12 with record drought conditions and low snow levels (Figure 1).

Figure 1. A) Palmer short-term drought index from June 2011. B) Palmer short-term drought index from June 2012

A)

B)

Field Data

Significant variation in weather conditions and severe winters continue to impact this mule deer population. The winter of 2010-11 was the second severe winter experienced in this herd unit in 4 years, followed by one of the driest on record (2011-12), which resulted in very difficult summer conditions for deer. Because of high moisture levels from the summer/fall of 2011, most deer were in very good condition going into the winter of 2011-12, and resulted in a very large fawn crop during the spring/summer of 2012, most does producing twins. In a normal moisture year this would equate to a large increase in population. However, the summer of 2012 was under extreme drought designation, and does were unable to both build fat reserves and raise fawns. It appeared more does were in poor condition entering the 2012-13 winter, and fawns appeared to be smaller than previous years. Classification flights suggested the antler point

restriction implemented to increase buck ratios was successful. However harvest did not decrease from 2011 to 2012 as is normally expected during the first year of an antler point-restriction. The survey also yielded higher than average fawn ratios, the highest observed in nearly 15 years. Fawn ratios have been higher, on average since 2007-08, when compared to the period preceding 2007. Normally this would have resulted in a quick return to population objective levels, but the population has experienced higher than average losses during severe winter events.

Harvest Data

The 2011 hunting season saw the lowest hunter success (38%) experienced in the Baggs herd since 1997. In 2012, despite the antler point restriction, our harvest success increased to 47%. This increase can be attributed to variation in hunting weather conditions, deer distribution, activity levels of deer, and an increasing population of deer. In 2011 the high moisture levels increased forage production, and allowed deer to be widely scattered, whereas 2012 produced less forage and concentrated deer in the areas with moisture. In addition, deer seemed to spend more time feeding and moving in these areas. We believe these factors led to animals being more vulnerable to harvest and thus increasing the harvest success.

Population

The current postseason population model estimates for 2012 suggest we are still below objective at around 16,300 animals. Despite the SCJ, SCA model having the lowest relative AICc value, we chose the TSJ, CA model based on what we believe to be a better representation of the actual population trend. The results of this model are consistent with harvest statistics, hunter satisfaction, plausibility, and field observations. The SCJ, SCA model shows a population that was nearly 3 times over objective before the winter of 2007-08 and that does not seem to be biologically feasible.

Discontent of hunters in 2010 and 2011, coupled with the TSJ, CA model population estimate seems to suggest our current management goal of increasing deer numbers in this herd unit is reasonable. The spreadsheet model seems to be a useful tool to estimate trend for this herd unit, but should be viewed with some caution without an independent estimate of population size.

Management Summary

The 2013 conservative season and use of an antler point restriction will allow for continued growth of this deer population, and will address the main concerns raised by sportsmen, mainly lower than desired deer numbers and buck ratios. Despite the observed increase in buck ratios from 2011 to 2012, we agreed to maintain the antler point restriction for 2 years. The 2013 hunting season will be the final year of the point restriction. Higher buck ratios did allow us to increase the number of days available to hunters to hunt in Hunt Area 82 for 2013, but the additional days fall within the middle of the week and will significantly increase harvest. In order to address lower deer numbers in the Baggs herd, general seasons are for antlered deer, only, and all doe/fawn licenses have been eliminated. Doe harvest will be restricted until deer numbers are at or above objective.

In an effort to increase youth opportunities, five days of youth only deer hunting will be offered in 2013 following the general season in Area 82, and two extra days in Area 100. Youth are permitted to harvest any deer, statewide, including all bucks, does, and fawns.

Management Evaluation

Current Management Objective: 4,000

Management Strategy: Recreational

2012 Postseason Population Estimate: ~2,700

2013 Proposed Population Estimate: ~2,700

The management objective for the Steamboat mule deer herd is 4,000 animals post-season under a recreational management scenario. The objective for this population was set in 1991.

Herd Unit Issues

The 2012 modeled post-season population estimate for this herd is roughly 2,700 deer with a declining trend since the population was estimated to be around 4,500 deer in 2007. The downward trend seen in this population can be attributed to three main causes. Increased doe harvest was initiated in 2009 and 2010 due to the population being over objective, which was

followed by severe winter conditions during the 2010-2011 winter, which resulted in approximately 40% mortality on collared adult does. Since that time, low fawn production largely caused by drought conditions in the herd unit has not allowed this population to rebound.

Weather

Deer wintering in the Leucite Hills area of the herd unit suffered severe winter mortality during the 2010-2011 winter. Based on data from GPS collars deployed by the BLM Rock Springs Field Office, adult doe deer wintering in the Leucite Hills experienced nearly 40% mortality during that winter. However, observed yearling buck to doe ratios were much higher than expected in the 2011 postseason classifications, which would indicate good overwinter survival, when collar data indicated otherwise. The most likely explanation for this is that because funds were not available for an aerial classification flight in 2011, a larger proportion of the classification sample came from the area near the Green River, which tends to have higher fawn production than the Leucite Hills portion of the herd and experienced milder winter conditions during the 2010-2011 winter. While the 2011-2012 winter was substantially milder than the previous winter, which allowed for better overwinter survival.

Habitat

No habitat transects targeting deer range were conducted within the Steamboat Herd Unit. However, the summer of 2012 was one of the driest summers on record in Wyoming. Since many of the deer in this herd summer at lower elevations than deer in other populations, the drought conditions during 2012 were felt especially strongly by this population. The low moisture levels during the fawn rearing portion of 2012 are probably the reason behind the extremely low fawn ratios seen in the 2012 classifications.

Field Data

Classifications on this herd were conducted with the aid of a helicopter during December 2012, when this herd was flown in conjunction with the Steamboat elk herd. The majority of deer observed during the classification flights were deer wintering in the Leucite Hills area north of the town of Superior. A total of 513 deer were classified from the air in 2012, this compares to an average of 1,215 deer classified each year when the herd was also sampled from the air between 2008 and 2010 with a similar effort expenditure. The resulting observed ratios from the 2012 classification efforts were 40 fawns per 100 does and 20 total bucks per 100 does, which included six yearling bucks per 100 does. The observed fawn to doe ratio of 40 fawns per 100 does in 2012 is the lowest ratio ever observed in this herd and is not sufficient for population maintenance and will not allow this population to grow towards its objective.

Harvest Data

The 2012 harvest was the second lowest recorded in recent history for this herd being only slightly better than the 2011 harvest. The harvest statistics of 28% harvest success and an average of 11.5 days per animal harvested while better than the statistics from the 2011 hunting season still suggest that the deer population in HA 131 is still recovering from the 2010-2011

winter. These harvest statistics along with fawn recruitment data and collar data indicate that deer numbers in HA 131 are lower now than they were several years ago.

Population

The model for the Steamboat herd tracks fairly well with observed data despite the fact that preliminary results from a GPS collar study suggest that roughly 1/3 of the deer wintering in the Leucite Hills are summering in the Sublette herd unit. The collars from that study are due to drop off during the summer of 2013, which will allow for a more detailed analysis of the movements between the Steamboat and Sublette deer herds. The time-specific juvenile survival model was used for this population since it seem to best match field observations.

Management Summary

The 2013 season for the Steamboat deer herd maintains a conservative general season and a limited number of doe fawn licenses directed at agricultural areas within the hunt urea that are experiencing deer damage issues. The 2013 general season will run for four days starting on a Tuesday and ending on Friday. This is being done in response to low hunter success, high days per animal harvested and a lower deer population in HA 131 during the 2011 and 2012 hunting seasons. The general season also includes a six day youth season that will overlap the general season but will include the weekend. This is being done to allow youth hunters an opportunity to hunt without conflicting with school. In addition to the general season, the 2013 hunting season includes 50 Type 7 doe fawn licenses in areas where deer damage to private land is a concern, similar to the 2012 season.
